Abstract

For a given point set S in a plane, we develop a distributed algorithm to compute the α -shape of S . α -shapes are well known geometric objects which generalize the idea of a convex hull, and provide a good definition for the shape of S . We assume that the distances between pairs of points which are closer than a certain distance $r > 0$ are provided, and we show constructively that this information is sufficient to compute the alpha shapes for a range of parameters, where the range depends on r .

Such distributed algorithms are very useful in domains such as sensor networks, where each point represents a sensing node, the location of which is not necessarily known.

We also introduce a new geometric object called the Delaunay-Čech shape, which is geometrically more appropriate than an α -shape for some cases, and show that it is topologically equivalent to α -shapes.

1 Introduction

Many applications call for detecting and tracking the boundary of a dynamically changing space of interest [4] [3]. We would expect any algorithm performing the task to include the following important properties: 1) the boundary output is geometrically close to the actual boundary, and 2) the interior of the boundary is topologically faithful to the original space. It is often the case that we are only given random samples from the space. We may then reconstruct the space by first placing balls of a certain radius around these points, and then by taking the union of these balls. A good exposition on relationship amongst the sampling density, the geometry of the underlying space, and the radius of the balls may be found in [10].

In this paper, we start with the assumption that the union of the balls described above is a good approximation to the space of interest. Note that in some cases, this is by design. For example, in the case of systematic failures in sensor networks [3], the failure in the nodes is caused by a spatially propagating phenomenon, and our aim is to track its boundary. In

this case, we construct a space by taking the union of balls of radius $r_c/2$ around each node, where r_c is its radius of communication. The radius of communication is the distance within which two nodes can communicate with each other.

The problem may also be viewed as one of computing the boundary of a set of points, provided with some geometric information. Given the binary information, about nodes pair-wise location within a certain distance, distributive algorithms exist to compute such a boundary [2]. These algorithms are, unfortunately relatively slow, on account of the need for a global structure to reach a decision on the membership of a node or of an edge to the complex boundary. If on the other hand, we are provided with all pair-wise distances of nodes within a neighborhood, the above decision may be locally made by constructing an associated α -shape.

Given a set of points S in a plane, the α -shape introduced in [5] gives a generalization of the convex hull of S , and an intuitive definition for the shape of points. More importantly, an α -shape is the boundary of an alpha complex, which has the same topology as that of the union of balls. This relation amongst α -shape, alpha complex and the union of balls is contingent on certain relations between their parameters. We discuss this in detail in Section 2.1. Such topological guarantees cannot be provided by the boundary computed in [2].

The Delaunay triangulation gives sufficient information to compute the alpha complex, and hence its boundary, the α -shape. If we only require the α -shape, less information would be necessary. The work in [7] shows that a global Delaunay triangulation is not necessary, and the alpha shape can be computed using local Delaunay triangulations. Given the edge lengths of a geometric graph, [7] constructs the local Delaunay triangulation by first building local coordinates and then computing the Delaunay triangulation. Computing the local coordinates, is however not robust and requires a high density of nodes for accuracy. When given the edge length information, we show that even local Delaunay triangulation is not necessary.

When there is a sufficient density of nodes, computing local coordinates is accurate (probabilistically), and distributed algorithms exist for computing modified versions of Delaunay triangulation [1, 9]. In this case, we define a certain *Delaunay-Čech triangulation*, which contains an alpha complex, and which we show to be homotopy equivalent. For boundary tracking-based applications, the boundary of Delaunay-Čech triangulation will serve as a better geometric approximation to the boundary, while preserving the topological features.

Our contributions in this article are:

- Given the distances between pairs of nodes whenever they are closer than $r_c > 0$, we develop an algorithm to compute the α -shape for a range of parameters, where this range depends on r_c .
- We introduce the Delaunay-Čech triangulation, defined in Section 2.2, and show that

it is homotopy equivalent to the alpha complex.

The remainder of the paper is organized as follows, in Section 2, we provide some background information, along with a formulation of the problem. We describe the distributed algorithm for computing an α -shape in Section 3. The Delaunay-Čech triangulation and the Delaunay-Čech shape are defined in Section 2.2, while the proof of its topological equivalence to the alpha complex is given in Section 4. We conclude in Section 5 with some remarks.

2 Preliminaries

2.1 Alpha complex and α -shape

Consider a set of nodes $V \subset \mathbb{R}^2$, and a parameter r . Let V_i be the voronoi cell associated with node $v_i \in V$ in the voronoi decomposition of V . Define an alpha cell (α -cell) of v_i as $\alpha(v_i, r) = V_i \cap B(v_i, r)$ where $B(v_i, r/2)$ is the closed ball of radius $r/2$ around v_i . The alpha complex, A_r (we are assuming V is implied in this notation), is defined as the nerve complex of the alpha cells, i.e., $(v_0, v_1, \dots, v_k)$ spans a k -simplex in A_r if $\bigcap_i \alpha(v_i) \neq \emptyset$. Since the alpha cells are convex, the nerve theorem [8, 11] implies that the alpha complex has the same homotopy type as the union of the alpha cells, which in turn is equal to the union of the balls $B(v_i, r/2)$.

Given a set of nodes $V \subset \mathbb{R}^2$ [†], and a parameter $r > 0$, the alpha shape, ∂A_r , is a 1-dimensional complex which generalizes the convex hull of V . To simplify the notation, we use (v_i, v_j) to denote an edge in a graph, a 1-simplex in a complex or the underlying line segment. A 1-simplex (v_i, v_j) belongs to ∂A_r if and only if a circle of radius $r/2$ passing through v_i and v_j does not contain any other node inside it. By “inside” a circle, we mean the interior of the ball to which this circle is a boundary. We say that such a circle satisfies the “ α -condition”. ∂A_r also contains all the nodes $\{v_j\}$ such that a circle of radius r passing through v_j satisfies the α -condition.

For a 2-dimensional simplicial complex K , we define the boundary of K to be the union of all the 1-simplices (along with their faces), where each is a face of at most one 2-simplex, and all 0-simplices which are not faces of any simplex in K . The alpha shape ∂A_r is the boundary of the alpha complex A_r [6].

2.2 Delaunay-Čech Shape

For a set of nodes $V \subset \mathbb{R}^2$ and a parameter $r > 0$, define the geometric graph $G_r = (V, E)$ to be the set of vertices (V) and edges (E), where $e = (v_i, v_j)$ is in E if the distance between v_i and v_j is less than or equal to r . Let $\check{C}(V, r)$ denote the Čech complex with parameter r (the nerve complex of the set of balls $\{B(v_i, r/2)\}$) and let $DT(V)$ be the

[†]The alpha shape is generally defined for points in $\mathbb{R}^k$ for any dimension k .

Delaunay triangulation of V . We define the Delaunay-Čech complex $D\check{C}_r$ with parameter r as $D\check{C}_r = DT(V) \cap \check{C}(V, r)$. We will show in Section 4, that $D\check{C}_r$ is homotopy equivalent to A_r . We call the boundary of $D\check{C}_r$, denoted by $\partial D\check{C}_r$ the Delaunay-Čech shape.

3 Computing the alpha shape of points in $\mathbb{R}^2$

In order to compute ∂A_r , we take each edge in G_r and check if it is in ∂A_r . If an edge $e = (v_i, v_j)$ belongs to ∂A_r , then the length of the line segment (v_i, v_j) is less than or equal to r . Otherwise, the α -condition cannot be satisfied. Edge e hence also belongs to G_r , and consequently, checking for all the edges in G_r is sufficient to compute ∂A_r .

Given an edge $e = (v_i, v_j)$, there are two circles of radius r passing through v_i and v_j . Let us call these circles $\mathcal{C}$ and $\mathcal{C}'$ (see Figure 1(a)). The α -condition is satisfied if and only if at most one of $\mathcal{C}$ and $\mathcal{C}'$ contains node(s) inside.

We consider all the nodes in $\mathcal{N}_i \cap \mathcal{N}_j$ (neighbors common to both v_i and v_j), and perform a series of tests to verify their location inside $\mathcal{C}$ and $\mathcal{C}'$. It is simple to see that considering nodes only in $\mathcal{N}_i \cap \mathcal{N}_j$ is sufficient. The diameter of both $\mathcal{C}$ and $\mathcal{C}'$ is r . If v_k lies in one of the circles, the distance between v_k and either of v_i and v_j is less than r , and hence, v_k is a neighbor to both.

We now derive the following:

1. A test to see if a node lies in both circles $\mathcal{C}$ and $\mathcal{C}'$. This immediately determines that e does not belong to ∂A_r .
2. A test to see if a node lies in exactly one of the circles $\mathcal{C}$ and $\mathcal{C}'$.
3. Given that there exists at least one node in one of the circles, a test to see if a subsequent node lies in the other. This also, immediately determines that e does not belong to ∂A .

Let the angle subtended by the chord $v_i v_j$ on the bigger arc (of either circle, see Figure 1(a)) be θ , hence making the angle subtended on the smaller arc $\pi - \theta$. The angle which the chord subtends at the center, ω , may easily be computed using the law of cosines, and θ is equal to $\omega/2$.

Let $v_k \in \mathcal{N}_i \cap \mathcal{N}_j$, and let $\angle v_i v_k v_j = \phi_k$. Then, if $\phi_k > \pi - \theta$, v_k lies inside both circles, and we immediately know that e does not belong to ∂A_r . If $\phi \leq \theta$, it lies inside neither circle. Let v_k be the first node satisfying $\theta < \phi \leq \pi - \theta$. Then v_k lies in one of the circle. Without loss of generality, we assume v_k lies in $\mathcal{C}$.

Let v_l be any subsequent node satisfying $\theta < \phi_l \leq \pi - \theta$. If v_l is not a neighbor of v_k , then v_l lies in $\mathcal{C}'$, since any two nodes inside a circle of diameter r will be neighbors. If v_k and v_l

are neighbors, we know the length $\|(v_kv_l)\|$. Using the law of cosines, we compute the angle $\angle v_kv_iv_l$ which we call β . If $\beta = \angle v_kv_iv_j + \angle v_lv_iv_j$, v_l lies in $\mathcal{C}'$, and if $\beta = |\angle v_kv_iv_j - \angle v_lv_iv_j|$, v_l lies in $\mathcal{C}$. Figure 1(b) demonstrates this relationship between the angles.

computing the α -shape
At each edge $e = (v_i, v_j)$ in G, compute θ for each $v_k \in \mathcal{N}_i \cap \mathcal{N}_j$ compute ϕ_k if $\phi_k > \pi - \theta$ $e \notin \partial A$, terminate if $\phi_k \leq \theta$, continue to next node if $\theta < \phi \leq \pi - \theta$ is v_k the first node satisfying this condition? assign v_k to $\mathcal{C}$ else compute β if $\beta = \angle v_kv_iv_j - \angle v_lv_iv_j$ continue to next node else $e \notin \partial A$, terminate $e \in \partial A$

Table 1: Algorithm for computing the α -shape. Note that all the computations require only local information.

The algorithm terminates when we determine that both circles $\mathcal{C}$ and $\mathcal{C}'$ contain at least one node, or there are no more nodes in $\mathcal{N}_i \cap \mathcal{N}_j$ to consider. In the former case, the edge e does not belong to ∂A_r and in the latter, e belongs to ∂A_r . Clearly, we can use the same algorithm to compute the α -shape for any parameter $0 < q \leq r$. The algorithm is summarized in Table 1. Figure 2 shows ∂A_r for a set of points in $\mathbb{R}^2$ computed using the algorithm in Table 1. The shaded region in the Figure is the union of balls of radius $r/2$ centered at each point. Note that the α -shape is a boundary of an object which is homotopy equivalent to the shaded region.

4 Relation between $D\check{C}_r$ and A_r

Consider the Delaunay-Čech complex $D\check{C}_r$ as defined in Section 2.2, and the α -complex A_r , as defined in Section 2.1. We will show that $D\check{C}_r$ has the same homotopy type as A_r , by show-

Figure 1: (a) shows the cycles $\mathcal{C}$ and $\mathcal{C}'$ which pass through v_i and v_j . ϕ_k satisfies $\theta \leq \phi \leq \pi - \theta$ and v_k lies in $\mathcal{C}$. (b) shows the angle relationships. When v_l also lies in $\mathcal{C}$, then $\beta = |\angle v_k v_i v_j - \angle v_l v_i v_j|$, and if v_l lies in $\mathcal{C}'$, $\beta = \angle v_k v_i v_j + \angle v_l v_i v_j$

Figure 2: α -shape with parameter $r_c/2$ for a set of points in $\mathbb{R}^2$ computed using algorithm in Table 1. The shaded region is the union of balls of radius $r_c/2$ centered at each point.

ing that there exists a bijective pairing between the 1-simplices and 2-simplices in $D\check{C}_r \setminus A_r$, such that the pairing describes a homotopy collapse. Note that both A_r and $D\check{C}_r$ do not contain any simplices of dimension greater than 2. Figure 3 shows such a homotopy collapse.

Figure 3: Homotopy collapse of an edge into an adjacent 2-simplex

Let $F(G_r)$ be the flag complex of G_r . Define the complex U_r as $U_r = DT(V) \cap F(G_r)$.

Figure 4: Examples of the triangle sets $\mathcal{T}_e^{r_c/2}$ and $\mathcal{T}_e^{\pi/2}$. The circles in (a) have are centered at the nodes with radius $r/2$. Since the circum-radius is less than $r/2$, the circles have a common intersection with positive area.

Since the Čech complex $\check{C}(V, r)$ is a subcomplex of $F(G_r)$, $D\check{C}_r$ is a subcomplex of U_r .

Let $\mathcal{T}_e$ denote the set of all 2-simplices to which e is a face in U_r , $\mathcal{T}_e^{r_c/2} \subseteq \mathcal{T}_e$ denote the 2-simplices in $\mathcal{T}_e$ with circum-radius less than or equal to $r/2$, and $\mathcal{T}_e^{\pi/2} \subseteq \mathcal{T}_e$ denote the 2-simplices in $\mathcal{T}_e$ such that the angle opposite e is greater than $\pi/2$. Figure 4 shows examples of triangles with these properties.

In order to show the existence of a pairing, we first analyze the triangles surrounding an edge $e \in A_r$. The following lemma characterizes the 2-simplices in A_r in terms of their circum-radius.

Lemma 4.1 *A simplex (v_1, v_2, v_3) in U_r is in A_r iff the circum-radius of the triangle (v_1, v_2, v_3) is less than or equal to $r/2$.*

Proof Since $U_r \subseteq DT(V)$, $(v_1, v_2, v_3) \in U_r \Rightarrow (v_1, v_2, v_3) \in DT(V)$. The circumradius is less than or equal to $r/2$, iff circumcenter belongs to all α -cells $\alpha(v_1)$, $\alpha(v_2)$ and $\alpha(v_3)$. This results in the three α -cells having a non-empty intersection, hence $(v_1, v_2, v_3) \in A_r$. ■

Lemmas 4.2 and 4.3 together impose conditions on cardinality of the sets $\mathcal{T}_e^{r_c/2}$ and $\mathcal{T}_e^{\pi/2}$. We utilize these conditions in Lemma 4.1 to show the existence of the pairing.

Lemma 4.2 *Denote by m_e the midpoint of the 1-simplex $e \in U_r$. m_e is a witness for e iff $\mathcal{T}_e^{\pi/2} = \emptyset$*

Proof m_e is a witness for e iff there does not exist any other node inside the circle with e as the diameter (illustrated in Figure 5(a)). This occurs if and only if the angle opposite e in any incident triangle is acute. ■

(a) Construction for Lemma 4.2.

(b) Construction for Lemma 4.4

Figure 5:

Lemma 4.3 *Consider the following statements*

- $S_1 : \mathcal{T}_e^{\pi/2} = \emptyset$
- $S_2 : \mathcal{T}_e^{r/2} \neq \emptyset$
- $S_3 : e \in A_r$

$S_1 \vee S_2$ is a necessary and sufficient condition for S_3 .

Proof Let $e = (v_1, v_2)$. For sufficiency: from Lemma 4.2, S_1 implies m_e is a witness for v_1 and v_2 , and S_2 implies $\exists$ a witness (the circumcenter of one of the triangles in $\mathcal{T}_e^{r/2}$). For necessity: if S_3 is true, then there exists a witness for e . If m_e is a witness, then S_1 is true. If m_e is not a witness, then e shares a witness with a 2-simplex which is in A_r . From Lemma 4.1, this implies $\mathcal{T}_e^{r/2} \neq \emptyset$. Therefore, S_2 is true. ■

The above Lemma suggests the existence or non-existence of types of triangles surrounding an edge in A_r . Lemma 4.4 and Theorem 4.1 further refine this relationship, and precisely identify the triangle to be removed when an edge is removed from $D\check{C}_r$.

Lemma 4.4 *If $\mathcal{T}_e^{\pi/2} \neq \emptyset$, then $|\mathcal{T}_e^{\pi/2}| = 1$.*

Proof Suppose $\mathcal{T}_e^{\pi/2} \neq \emptyset$. Let $\tau \in \mathcal{T}_e^{\pi/2}$, and let the angle opposite e in τ be ϕ with $\phi > \pi/2$ (see Figure 5(b)). Let $\tau_1 \neq \tau$ be incident on e , with v being the opposite vertex. Since $\tau \in U_r$, v does not lie inside the circum-center of τ . This implies that the angle opposite e in τ_1 is less than $\pi - \phi$ which is less than $\pi/2$. ■

Let $C_k(K)$ denote the k -simplices in the complex K .

[†]we use the notation (v_1, v_2, v_3) to denote both the simplex and the underlying triangle

Figure 6: Figure shows the homotopy equivalence between $A_{r_c/2}(V)$ and $D\check{C}_{r_c/2}(V)$. The shaded region is R_c . Note that $D\check{C}_{r_c/2}(V)$ is a better geometric approximation to R_c than $A_{r_c/2}(V)$.

Theorem 4.1 *Let $\mathcal{T}_R = C_2(D\check{C}_r) \setminus C_2(A_r)$ and $\mathcal{E}_R = C_1(D\check{C}_r) \setminus C_1(A_r)$. There exists a bijective pairing $P : \mathcal{E}_R \rightarrow \mathcal{T}_R$ such that e is a face of $P(e)$.*

Proof Let $e \in D\check{C}_r$ but $e \notin A_r$, from Lemma 4.3, $\mathcal{T}_e^{r_c/2} = \emptyset$ and $\mathcal{T}_e^{\pi/2} \neq \emptyset$. Since we assume $e \notin A_r$, e cannot be a face of any 2-simplex in A_r . Owing to the condition $\mathcal{T}_e^{r_c/2} = \emptyset$, Lemma 4.1 ensures that this is indeed the case. Also, from Lemma 4.4, $|\mathcal{T}_e^{\pi/2}| = 1$. Let $\tau \in \mathcal{T}_e^{\pi/2}$. Note that τ is unique, and $\tau \notin A_r$. Further, since τ is an obtuse triangle, $\tau \in \check{C}(V, r)$, and this implies $\tau \in D\check{C}_r$. The pairing P is then defined as $P(e) = \tau$. ■

For any simplicial complex K , let σ_1 and σ_2 be simplices of dimension 1 and 2 such that σ_1 is a face of σ_2 . Then, there exists a deformation retraction $F_{\sigma_1} : K \rightarrow K \setminus (\sigma_1 \cup \text{Int}(\sigma_2))$, which “collapses” σ_1 into σ_2 . Therefore, K is homotopy equivalent to $K \setminus (\sigma_1 \cup \text{Int}(\sigma_2))$.

The removal of edges $\mathcal{E}_R$ and triangles $\mathcal{T}_R$ describes a finite sequence of deformation retractions via the pairing P . When we collapse all the edges into their paired triangles, the resulting complex is A_r . Each collapse is a homotopy equivalence, and a composition of homotopy equivalences is a homotopy equivalence. This leads us to our main theorem:

Theorem 4.2 *The complexes $D\check{C}_r$ and A_r are homotopy equivalent.*

Figure 6 illustrates the above theorem using an example. Note that A_r and $D\check{C}_r$ are homotopy equivalent to each other and both are homotopy equivalent to R_c (the shaded region). Further, as seen, $D\check{C}_r$ is a better geometric approximation to R_c than A_r . This is simply because A_r is a sub-complex of $D\check{C}_r$.

5 Conclusion

The algorithm described in Section 3 takes the edge lengths as inputs and outputs the alpha shapes. We make no further assumptions on the node density, and we need not compute any

coordinates. The decision about an edge belonging to an α -shape is carried out by only looking at the local information, i.e., considering only the points within a certain distance, and may therefore be implemented distributively. In Section 2.2, we define the Delaunay-Čech complex which contains the alpha complex. Its boundary, defined as a Delaunay-Čech shape, is therefore a better geometric approximation for the union of balls with an appropriate radius. We also show in Section 4 that, like the α -shape, the Delaunay-Čech shape remains topologically faithful to the underlying space.
